On Nearly Orthogonal Lattice Bases and Random Lattices

Ramesh Neelamani, Sanjeeb Dash, and Richard G. Baraniuk *

September 18, 2006

Abstract

We study lattice bases where the angle between any basis vector and the linear subspace spanned by the other basis vectors is at least $\frac{\pi}{3}$ radians; we denote such bases as “nearly orthogonal”. We show that a nearly orthogonal lattice basis always contains a shortest lattice vector. Moreover, we prove that if the basis vector lengths are “nearly equal”, then the basis is the unique nearly orthogonal lattice basis up to multiplication of basis vectors by $\pm 1$. We also study random lattices generated by the columns of random matrices with $n$ rows and $m \leq n$ columns. We show that if $m \leq cn$, with $c \approx 0.071$, then the random matrix forms a nearly orthogonal basis for the random lattice with high probability for large $n$ and almost surely as $n$ tends to infinity. Consequently, the columns of such a random matrix contain the shortest vector in the random lattice. Finally, we discuss an interesting JPEG image compression application where nearly orthogonal lattice bases play an important role.

Keywords

lattices, shortest lattice vector, random lattice, JPEG, compression.

1 Introduction

Lattices are regular arrangements of points in space that are studied in numerous fields, including coding theory, number theory, and cryptography [1, 15, 17, 21, 24]. Formally, a lattice $\mathcal{L}$ in $\mathbb{R}^n$ is the set of all linear integer combinations of a finite set of vectors; that is, $\mathcal{L} = \{u_1 b_1 + u_2 b_2 + \cdots + u_m b_m | u_i \in \mathbb{Z}\}$ for some $b_1, b_2, \ldots, b_m$ in $\mathbb{R}^n$. The set of vectors $\mathcal{B} = \{b_1, b_2, \ldots, b_m\}$ is said to span the lattice $\mathcal{L}$. An independent set of vectors that spans $\mathcal{L}$ is a basis of $\mathcal{L}$. A lattice is said to be $m$-dimensional ($m$-D) if a basis contains $m$ vectors.

In this paper we study the properties of lattice bases whose vectors are “nearly orthogonal” to one another. We define a basis to be $\theta$-orthogonal if the angle between any basis vector and the linear subspace spanned by the remaining basis vectors is at least $\theta$. A $\theta$-orthogonal basis is deemed to be nearly orthogonal if $\theta$ is at least $\frac{\pi}{3}$ radians.

We derive two simple but appealing properties of nearly orthogonal lattice bases.

1. A $\frac{\pi}{3}$-orthogonal basis always contains a shortest non-zero lattice vector.

Baraniuk were supported by grants from NSF, AFOSR, ONR, DARPA, and the Texas Instruments Leadership Universities program.
2. If all vectors of a $\theta$-orthogonal $(\theta > \frac{\pi}{3})$ basis have lengths less than $\frac{\sqrt{3}}{\sin \theta + \sqrt{3} \cos \theta}$ times the length of the shortest basis vector, then the basis is the unique $\frac{\pi}{3}$-orthogonal basis for the lattice (up to multiplication of basis vectors by $\pm 1$).

Gauss [13] proved the first property for 2-D lattices. We prove (generalizations of) the above properties for $m$-D lattices for arbitrary $m$.

We also study lattices generated by a set of random vectors; we focus on vectors comprising Gaussian or Bernoulli $(\pm \frac{1}{\sqrt{n}})$ entries. The set of vectors and the generated lattice are henceforth referred to as a random basis and a random lattice, respectively. Random bases and lattices find applications in coding [7] and cryptography [28]. We prove an appealing property of random lattices.

If a random lattice $\mathcal{L}$ in $\mathbb{R}^n$ is generated by $m \leq cn$ ($c \approx 0.071$) random vectors, then the random vectors form a $\frac{\pi}{3}$-orthogonal basis of $\mathcal{L}$ with high probability at finite $n$ and almost surely as $n \to \infty$.

Consequently, the shortest vector in $\mathcal{L}$ is contained by the random basis with high probability.

We exploit properties of nearly orthogonal bases to solve an interesting digital image processing problem. Digital color images are routinely subjected to compression schemes such as the Joint Photographic Experts Group (JPEG) standard [26]. The various settings used during JPEG compression of an image—termed as the image’s JPEG compression history—are often discarded after decompression. For compression of images which were earlier in JPEG-compressed form, it is useful to estimate the discarded compression history from their current representation. We call this problem JPEG compression history estimation (JPEG CHEst). The JPEG compression step maps a color image into a set of points contained in a collection of related lattices [23]. We show that the JPEG CHEst problem can be solved by estimating the nearly orthogonal bases spanning these lattices. Then, we invoke the derived properties of nearly orthogonal bases in a heuristic to solve the JPEG CHEst problem [23].

Lattices that contain nearly orthogonal bases are somewhat special\(^1\) because there exist lattices without any $\frac{\pi}{3}$-orthogonal basis (see (4) for an example). Consequently, the new properties of nearly orthogonal lattice bases in this paper cannot be exploited in all lattice problems.

The paper is organized as follows. Section 2 provides some basic definitions and well-known results about lattices. Section 3 formally states our results on nearly orthogonal lattice bases and Section 4 furnishes the proofs for the results in Section 3. Section 5 identifies new properties of random lattices. Section 6 describes the role of nearly orthogonal bases in the solution to the JPEG CHEst problem. Section 7 concludes with a discussion of some limitations of our results and future research directions.

### 2 Lattices

Consider an $m$-D lattice $\mathcal{L}$ in $\mathbb{R}^n$, $m \leq n$. By an ordered basis for $\mathcal{L}$, we mean a basis with a certain ordering of the basis vectors. We represent an ordered basis by an ordered set, and also by a matrix whose columns define the basis vectors and their ordering. We use the braces ($\{,\}$) for ordered sets (for example, $(b_1, b_2, \ldots, b_m)$) and $\{,\}$ otherwise (for example, $\{b_1, b_2, \ldots, b_m\}$). For vectors $u, v \in \mathbb{R}^n$, we use both $u^Tv$ (with $T$ denoting matrix or vector transpose) and $\langle u, v \rangle$ to denote the inner product of $u$ and $v$. We denote the Euclidean norm of a vector $v$ in $\mathbb{R}^n$ by $\|v\|$.

Any two bases $B_1$ and $B_2$ of $\mathcal{L}$ are related (when treated as $n \times m$ matrices) as $B_1 = B_2 \mathcal{U}$, where $\mathcal{U}$ is a $m \times m$ unimodular matrix; that is, an integer matrix with determinant equal to $\pm 1$.

\(^1\)However, our random basis results suggest nearly orthogonal bases occur frequently in low-dimensional lattices.
The closest vector problem (CVP) and the shortest vector problem (SVP) are two closely related, fundamental lattice problems [1, 2, 10, 15]. Given a lattice \( \mathcal{L} \) and an input vector (not necessarily in \( \mathcal{L} \)), CVP aims to find a vector in \( \mathcal{L} \) that is closest (in the Euclidean sense) to the input vector. Even finding approximate CVP solutions is known to be NP-hard [10]. The SVP seeks a vector in \( \mathcal{L} \) with the shortest (in the Euclidean sense) non-zero length \( \lambda(\mathcal{L}) \). The decision version of SVP is not known to be NP-complete in the traditional sense, but SVP is NP-hard under randomized reductions [2]. In fact, even finding approximately shortest vectors (to within any constant factor is NP-hard under randomized reductions [16, 20].

A shortest lattice vector is always contained by orthogonal bases. Hence, one approach to finding short vectors in lattices is to obtain a basis that is close (in some sense) to orthogonal, and use the shortest vector in such a basis as an approximate solution to the SVP. A commonly used measure to quantify the “orthogonality” of a lattice basis \( \{b_1, b_2, \ldots, b_m\} \) is its orthogonality defect [17],

\[
\prod_{i=1}^{m} \frac{\|b_i\|}{|\det([b_1, b_2, \ldots, b_m])|},
\]

with \( \det \) denoting determinant. For rational lattices (lattices comprising rational vectors), the Lovász basis reduction algorithm [17], often called the LLL algorithm, obtains an LLL-reduced lattice basis in polynomial time. Such a basis has a small orthogonality defect. There exist other notions of reduced bases due to Minkowski, and Korkin and Zolotarev (KZ) [15]. Both Minkowski-reduced and KZ-reduced bases contain the shortest lattice vector, but it is NP-hard to obtain such bases.

We choose to quantify a basis’s closeness to orthogonality in terms of the following new measures.

- **Weak \( \theta \)-orthogonality:** An ordered set of vectors \( \{b_1, b_2, \ldots, b_m\} \) is weakly \( \theta \)-orthogonal if for \( i = 2, 3, \ldots, m \), the angle between \( b_i \) and the subspace spanned by \( \{b_1, b_2, \ldots, b_{i-1}\} \) lies in the range \( [\theta, \frac{\pi}{2}] \). That is,

\[
\cos^{-1}\left(\frac{|\langle b_i, \sum_{j=1}^{i-1} \alpha_j b_j \rangle|}{\|b_i\| \|\sum_{j=1}^{i-1} \alpha_j b_i\|}\right) \geq \theta, \text{ for all } \alpha_j \in \mathbb{R} \text{ with } \sum_j |\alpha_j| > 0. \tag{1}
\]

- **\( \theta \)-orthogonality:** A set of vectors \( \{b_1, b_2, \ldots, b_m\} \) is \( \theta \)-orthogonal if every ordering of the vectors yields a weakly \( \theta \)-orthogonal set.

A (weakly) \( \theta \)-orthogonal basis is one whose vectors are (weakly) \( \theta \)-orthogonal. Babai [4] proved that an \( n \)-D LLL-reduced basis is \( \theta \)-orthogonal where \( \sin \theta = \left(\frac{\sqrt{2}}{4}\right)^n \); for large \( n \) this value of \( \theta \) is very small. Thus the notion of an LLL-reduced basis is quite different from that of a weakly \( \frac{\pi}{4} \)-orthogonal basis.

We will encounter \( \theta \)-orthogonal bases in random lattices in Section 5 and weakly \( \theta \)-orthogonal bases (with \( \theta \geq \frac{\pi}{4} \)) in the JPEG CHEst application in Section 6.

### 3 Nearly Orthogonal Bases: Results

This section formally states the two properties of nearly orthogonal lattice bases that were identified in the Introduction. We also identify an additional property characterizing unimodular matrices that relate two nearly orthogonal bases; this property is particularly useful for the JPEG CHEst application.

Obviously, in an orthogonal lattice basis, the shortest basis vector is a shortest lattice vector. More generally, given a lattice basis \( \{b_1, b_2, \ldots, b_m\} \), let \( \theta_i \) be the angle between \( b_i \) and the subspace spanned by
the other basis vectors. Then
\[ \lambda(\mathcal{L}) \geq \min_{i \in \{1, 2, \ldots, m\}} \|b_i\| \sin \theta_i. \]  
(2)

Therefore, a \(\theta\)-orthogonal basis has a basis vector whose length is no more than \(\lambda(\mathcal{L}) / \sin \theta\); if \(\theta = \frac{\pi}{3}\), this bound becomes \(\frac{2\lambda(\mathcal{L})}{\sqrt{3}}\). This shows that nearly orthogonal lattice bases contain short vectors.

Gauss proved that in \(\mathbb{R}^2\), every \(\frac{\pi}{3}\)-orthogonal lattice basis indeed contains a shortest lattice vector and provided a polynomial time algorithm to determine such a basis in a rational lattice; see [32] for a nice description. We first show that Gauss’s shortest lattice vector result can be extended to higher-dimensional lattices.

**Theorem 1** Let \(\mathcal{B} = (b_1, b_2, \ldots, b_m)\) be an ordered basis of a lattice \(\mathcal{L}\). If \(\mathcal{B}\) is weakly \((\frac{\pi}{3} + \epsilon)\)-orthogonal, for \(0 \leq \epsilon \leq \frac{\pi}{6}\), then a shortest vector in \(\mathcal{B}\) is a shortest non-zero vector in \(\mathcal{L}\). More generally,
\[ \min_{j \in \{1, 2, \ldots, m\}} \|b_j\| \leq \left\| \sum_{i=1}^{m} u_i b_i \right\| \quad \text{for all } u_i \in \mathbb{Z} \text{ with } \sum_{i=1}^{m} |u_i| \geq 1, \]  
(3)

with equality possible only if \(\epsilon = 0\) or \(\sum_{i=1}^{m} |u_i| = 1\).

**Corollary 1** If \(0 < \epsilon \leq \frac{\pi}{6}\), then a weakly \((\frac{\pi}{3} + \epsilon)\)-orthogonal basis contains every shortest non-zero lattice vector (up to multiplication by \(\pm 1\)).

Theorem 1 asserts that a \(\theta\)-orthogonal lattice basis is guaranteed to contain a shortest lattice vector if \(\theta \geq \frac{\pi}{3}\). In fact, the bound \(\frac{\pi}{3}\) is tight because for any \(\epsilon > 0\), there exist lattices where some \(\theta\)-orthogonal basis, with \(\theta = \frac{\pi}{3} - \epsilon\), does not contain the shortest lattice vector. For example, consider a lattice in \(\mathbb{R}^2\) defined by the basis \(\{b_1, b_2\}\), with \(\|b_1\| = \|b_2\| = 1\), and the angle between them equal to \(\frac{\pi}{3} - \epsilon\). Obviously \(b_2 - b_1\) has length less than 1.

For a rational lattice defined by some basis \(\mathcal{B}_1\), a weakly \(\frac{\pi}{3}\)-orthogonal basis \(\mathcal{B}_2 = \mathcal{B}_1 \mathcal{U}\), with \(\mathcal{U}\) polynomially bounded in size, provides a polynomial-size certificate for \(\lambda(\mathcal{L})\). However, we do not expect all rational lattices to have such bases because this would imply that \(\text{NP} = \text{co-NP}\), assuming \(\text{SVP}\) is \(\text{NP}\)-complete. For example, the lattice \(\mathcal{L}\) spanned by the basis
\[
\mathcal{B} = \begin{bmatrix}
1 & 0 & \frac{1}{2} \\
0 & 1 & \frac{1}{2} \\
0 & 0 & \frac{1}{\sqrt{2}}
\end{bmatrix}
\]  
(4)

does not have any weakly \(\frac{\pi}{3}\)-orthogonal basis. It is not difficult to verify that \([1 0 0]^T\) is a shortest lattice vector. Thus, \(\lambda(\mathcal{L}) = 1\). Now, assume that \(\mathcal{L}\) possesses a weakly \(\frac{\pi}{3}\)-orthogonal basis \(\widetilde{\mathcal{B}} = (b_1, b_2, b_3)\). Let \(\theta_1\) be the angle between \(b_2\) and \(b_1\), and let \(\theta_2\) be the angle between \(b_3\) and the subspace spanned by \(b_1\) and \(b_2\). Since \(b_1, b_2\) and \(b_3\) have length at least 1,
\[
\det(\widetilde{\mathcal{B}}) = \|b_1\| \|b_2\| \|b_3\| \sin \theta_1 \sin \theta_2 \sin \theta_3 \geq \sin^2 \frac{\pi}{3} = \frac{3}{4}.
\]  
(5)

But \(\det(\mathcal{B}) = \frac{1}{\sqrt{2}} < \det(\widetilde{\mathcal{B}})\), which shows that the lattice \(\mathcal{L}\) with basis \(\mathcal{B}\) in (4) has no weakly \(\frac{\pi}{3}\)-orthogonal basis.

Our second observation describes the conditions under which a lattice contains the unique (modulo permutations and sign changes) set of nearly orthogonal lattice basis vectors.
Figure 1: (a) The vectors comprising the lattice are denoted by circles. One of the lattice bases comprises two orthogonal vectors of lengths 1 and 1.5. Since $1.5 < \eta \left( \frac{\pi}{3} \right) = \sqrt{3}$, the lattice possesses no other basis such that the angle between its vectors is at least $\frac{\pi}{3}$ radians. (b) This lattice contains at least two $\frac{\pi}{3}$-orthogonal bases. One of the lattice bases comprises two orthogonal vectors of lengths 1 and 2. Here $2 > \eta \left( \frac{\pi}{3} \right)$, and this basis is not the only $\frac{\pi}{3}$-orthogonal basis.

**Theorem 2** Let $\mathcal{B} = (b_1, b_2, \ldots, b_m)$ be a weakly $\theta$-orthogonal basis for a lattice $\mathcal{L}$ with $\theta > \frac{\pi}{3}$. For all $i \in \{1, 2, \ldots, m\}$, if

$$\|b_i\| < \eta(\theta) \min_{j \in \{1, 2, \ldots, m\}} \|b_j\|,$$

with $\eta(\theta) = \frac{\sqrt{3}}{\sin \theta + \sqrt{3} \cos \theta}$, then any $\frac{\pi}{3}$-orthogonal basis comprises the vectors in $\mathcal{B}$ multiplied by $\pm 1$.

In other words, a nearly orthogonal basis is essentially unique when the lengths of its basis vectors are nearly equal. For example, both Fig. 1(a) and (b) illustrate 2-D lattices that can be spanned by orthogonal basis vectors. For the lattice in Fig. 1(a), the ratio of the lengths of the basis vectors is less than $\eta \left( \frac{\pi}{3} \right) = \sqrt{3}$. Hence, there exists only one (modulo sign changes) basis such that the angle between the vectors is greater than $\frac{\pi}{3}$. In contrast, the lattice in Fig. 1(b) contains many distinct $\frac{\pi}{3}$-orthogonal bases.

In the JPEG CHEst application [23], the target 3-D lattice bases in $\mathbb{R}^3$ are known to be weakly $\left( \frac{\pi}{3} + \epsilon \right)$-orthogonal but not $\left( \frac{\pi}{3} + \epsilon \right)$-orthogonal. Theorem 2 addresses the uniqueness of $\frac{\pi}{3}$-orthogonal bases, but not weakly $\frac{\pi}{3}$-orthogonal bases. To estimate the target lattice basis, we need to understand how different weakly orthogonal bases are related. The following theorem guarantees that for 3-D lattices, a weakly $\left( \frac{\pi}{3} + \epsilon \right)$-orthogonal basis with nearly equal-length basis vectors is related to every weakly orthogonal basis by a unimodular matrix with small entries.

**Theorem 3** Let $\mathcal{B} = (b_1, b_2, \ldots, b_m)$ and $\tilde{\mathcal{B}}$ be two weakly $\theta$-orthogonal bases for a lattice $\mathcal{L}$, where $\theta > \frac{\pi}{3}$. Let $\mathcal{U} = (u_{ij})$ be a unimodular matrix such that $\mathcal{B} = \tilde{\mathcal{B}} \mathcal{U}$. Define

$$\kappa \left( \mathcal{B} \right) = \left( \frac{2}{\sqrt{3}} \right)^{m-1} \frac{\max_{i \in \{1, 2, \ldots, m\}} \|b_i\|}{\min_{i \in \{1, 2, \ldots, m\}} \|b_i\|}.$$  

Then, $|u_{ij}| \leq \kappa \left( \mathcal{B} \right)$, for all $i$ and $j$.

For example, if $\mathcal{B}$ is a weakly $\theta$-orthogonal basis of a 3-D lattice with $\frac{\max_{i \in \{1, 2, 3\}} \|b_i\|}{\min_{i \in \{1, 2, 3\}} \|b_i\|} < 1.5$, then the entries of the unimodular matrix relating another weakly $\theta$-orthogonal basis $\tilde{\mathcal{B}}$ to $\mathcal{B}$ are either 0 or $\pm 1$.  

\begin{align*}
\kappa \left( \mathcal{B} \right) & = \left( \frac{2}{\sqrt{3}} \right)^{m-1} \frac{\max_{i \in \{1, 2, \ldots, m\}} \|b_i\|}{\min_{i \in \{1, 2, \ldots, m\}} \|b_i\|}.
\end{align*}
4 Nearly Orthogonal Bases: Proofs

4.1 Proof of Theorem 1

We first prove Theorem 1 for 2-D lattices (Gauss’s result) and then tackle the proof for higher-dimensional lattices via induction.

4.1.1 Proof for 2-D lattices

Consider a 2-D lattice with a basis $B = \{b_1, b_2\}$ satisfying the conditions of Theorem 1. Let $\theta'$ denote the angle between $b_1$ and $b_2$. Since $\frac{\pi}{4} \leq \theta' \leq \frac{\pi}{2}$ by assumption,

$$|\langle b_1, b_2 \rangle| = \|b_1\| \|b_2\| \cos \theta' \leq \frac{\|b_1\| \|b_2\|}{2}.$$  \hspace{1cm} (9)

The squared-length of any non-zero lattice vector $v = u_1 b_1 + u_2 b_2$, with $u_1, u_2 \in \mathbb{Z}$ and $|u_1| + |u_2| > 0$, equals

$$\|v\|^2 = |u_1|^2 \|b_1\|^2 + |u_2|^2 \|b_2\|^2 + 2u_1u_2 \langle b_1, b_2 \rangle \\
\geq |u_1|^2 \|b_1\|^2 + |u_2|^2 \|b_2\|^2 - 2|u_1||u_2| \langle b_1, b_2 \rangle \\
\geq |u_1|^2 \|b_1\|^2 + |u_2|^2 \|b_2\|^2 - |u_1| \|u_2\| \|b_1\| \|b_2\| \quad \text{(using (9))} \\
= (\|u_1\| \|b_1\| - |u_2| \|b_2\|)^2 + |u_1| \|u_2\| \|b_1\| \|b_2\| \\
\geq \min \left( \|b_1\|^2, \|b_2\|^2 \right),$$  \hspace{1cm} (10)

with equality possible only if either $|u_1| + |u_2| = 1$ or $\theta' = \frac{\pi}{3}$. This proves Theorem 1 for 2-D lattices.

4.1.2 Proof for higher-dimensional lattices

Let $k > 2$ be an integer, and assume that Theorem 1 is true for every $(k-1)$-D lattice. Consider a $k$-D lattice $\mathcal{L}$ spanned by a weakly $\left(\frac{\pi}{3} + \epsilon\right)$-orthogonal basis $(b_1, b_2, \ldots, b_k)$, with $\epsilon \geq 0$. Any non-zero vector in $\mathcal{L}$ can be written as $\sum_{i=1}^{k} u_i b_i$ for integers $u_i$, where $u_i \neq 0$ for some $i \in \{1, 2, \ldots, k\}$. If $u_k = 0$, then $\sum_{i=1}^{k} u_i b_i$ is contained in the $(k-1)$-D lattice spanned by the weakly $\left(\frac{\pi}{3} + \epsilon\right)$-orthogonal basis $(b_1, b_2, \ldots, b_{k-1})$. For $u_k = 0$, by the induction hypothesis, we have

$$\left\| \sum_{i=1}^{k} u_i b_i \right\| = \left\| \sum_{i=1}^{k-1} u_i b_i \right\| \geq \min_{j \in \{1, 2, \ldots, k-1\}} \|b_j\| \geq \min_{j \in \{1, 2, \ldots, k\}} \|b_j\|.$$ 

If $\epsilon > 0$, then the first inequality in the above expression can hold as equality only if $\sum_{i=1}^{k-1} |u_i| = 1$. If $u_k \neq 0$ and $u_i = 0$ for $i = 1, 2, \ldots, k-1$, then again

$$\left\| \sum_{i=1}^{k} u_i b_i \right\| \geq \|b_k\| \geq \min_{j \in \{1, 2, \ldots, k\}} \|b_j\|.$$ 

Again, it is necessary that $|u_k| = 1$ for equality to hold above.

Assume that $u_k \neq 0$ and $u_i \neq 0$ for some $i \in \{1, 2, \ldots, k-1\}$. Now $\sum_{i=1}^{k} u_i b_i$ is contained in the 2-D lattice spanned by the vectors $\sum_{i=1}^{k-1} u_i b_i$ and $u_k b_k$. Since the ordered set $(b_1, b_2, \ldots, b_k)$ is weakly $\left(\frac{\pi}{3} + \epsilon\right)$-orthogonal, the angle between the non-zero vectors $\sum_{i=1}^{k-1} u_i b_i$ and $u_k b_k$ lies in the interval $\left[\frac{\pi}{3} + \epsilon, \frac{\pi}{2}\right]$.
Invoking Theorem 1 for 2-D lattices, we have

\[
\left\| \sum_{i=1}^{k} u_i b_i \right\| \geq \min \left( \left\| \sum_{i=1}^{k-1} u_i b_i \right\|, \left\| u_k b_k \right\| \right) \\
\geq \min \left( \min_{j \in \{1, 2, \ldots, k-1\}} \left\| b_j \right\|, \left\| u_k b_k \right\| \right) \\
\geq \min_{j \in \{1, 2, \ldots, k\}} \left\| b_j \right\|. \tag{11}
\]

Thus, the set of basis vectors \( \{b_1, b_2, \ldots, b_k\} \) contains a shortest non-zero vector in the \( k \)-D lattice. Also, if \( \epsilon > 0 \), then equality is not possible in (11), and the second part of the theorem follows. \( \square \)

### 4.2 Proof of Theorem 2

Similar to the proof of Theorem 1, we first prove Theorem 2 for 2-D lattices and then prove the general case by induction.

#### 4.2.1 Proof for 2-D lattices

Consider a 2-D lattice in \( \mathbb{R}^n \) with basis vectors \( b_1 \) and \( b_2 \) such that the basis \( \{b_1, b_2\} \) is weakly \( \theta \)-orthogonal with \( \theta > \frac{\pi}{3} \). Note that for 2-D lattices, weak \( \theta \)-orthogonality is the same as \( \theta \)-orthogonality. Without loss of generality (w.l.o.g.), we can assume that \( 1 = \left\| b_1 \right\| \leq \left\| b_2 \right\| \). Further, by rotating the 2-D lattice, the basis vectors can be expressed as the columns of the \( n \times 2 \) matrix

\[
\begin{bmatrix}
1 & b_{21} \\
0 & b_{22} \\
\vdots & \vdots \\
0 & 0
\end{bmatrix}.
\]

Let \( \theta' \in [\theta, \frac{\pi}{2}] \) denote the angle between \( b_1 \) and \( b_2 \). Clearly,

\[
\cos \theta' = \frac{b_{21}}{\left\| b_2 \right\|} \quad \text{and} \quad \sin \theta' = \frac{b_{22}}{\left\| b_2 \right\|},
\]

Since (6) holds by assumption,

\[
\left\| b_2 \right\| < \frac{\sqrt{3} \left\| b_1 \right\|}{\sin \theta + \sqrt{3} \cos \theta} \leq \frac{\sqrt{3} \left\| b_1 \right\|}{\sin \theta' + \sqrt{3} \cos \theta'} = \frac{\sqrt{3}}{\frac{\left\| b_2 \right\|}{\left\| b_2 \right\|} + \frac{\sqrt{3} |b_{21}|}{\left\| b_2 \right\|}},
\]

where we have used the fact that \( \eta(\theta) \) is a non-decreasing function of \( \theta \) for \( \theta \in \left[ \frac{\pi}{3}, \frac{\pi}{2} \right] \). Therefore,

\[
|b_{22}| < \sqrt{3} \left( 1 - |b_{21}| \right). \tag{12}
\]

Let \( \{\bar{b}_1, \bar{b}_2\} \) denote another \( \frac{\pi}{3} \)-orthogonal basis for the same 2-D lattice. Using Theorem 1 and its Corollary 1, we infer that \( \{b_1, b_2\} \) contains every shortest lattice vector (multiplied by \( \pm 1 \)), and \( \{b_1, b_2\} \) and
\{\vec{b}_1, \vec{b}_2\} contain a common shortest lattice vector. Assume w.l.o.g. that \(\vec{b}_1 = \pm \vec{b}_1\) is a shortest lattice vector. Then, we can write
\[
[\vec{b}_1 \ \vec{b}_2] = [b_1 \ b_2] \begin{bmatrix} \pm 1 & u \\ 0 & \pm 1 \end{bmatrix}
\] with \(u \in \mathbb{Z}\).

To prove Theorem 2, we need to show that \(u = 0\).

Let \(\theta\) denote the angle between \(\vec{b}_1\) and \(\pm \vec{b}_2\). Then,
\[
\cos^2 \tilde{\theta} = \frac{|\langle \vec{b}_1, \vec{b}_2 \rangle|^2}{\|b_1\|^2 \|b_2\|^2} = \frac{(u \pm b_{21})^2}{(u \pm b_{21})^2 + b_{22}^2} > \frac{(u \pm b_{21})^2}{(u \pm b_{21})^2 + 3(1 - |b_{21}|)^2} \quad \text{(using (12))}
\]
\[
= \frac{1}{1 + \frac{3(1 - |b_{21}|)^2}{(u \pm b_{21})^2}}.
\]

(13)

If \(u \neq 0\), then
\[
|u \pm b_{21}| \geq |u| - |b_{21}| \geq 1 - |b_{21}| \geq 0 \quad \text{(from (12)).}
\]

Hence,
\[
|u \pm b_{21}|^2 \geq (1 - |b_{21}|)^2.
\]

Therefore, from (13) we have
\[
\cos^2 \tilde{\theta} > \frac{1}{4},
\]
which holds if and only if \(\tilde{\theta} < \frac{\pi}{3}\). Thus, \(\{\vec{b}_1, \vec{b}_2\}\) can be \(\frac{\pi}{3}\)-orthogonal only if \(u = 0\). This proves Theorem 2 for 2-D lattices.

### 4.2.2 Proof for higher-dimensional lattices

Let \(B\) and \(\vec{B}\) be two \(n \times k\) matrices defining bases of the same \(k\)-D lattice in \(\mathbb{R}^n\). We can write \(B = \vec{B}U\) for some integer unimodular matrix \(U = (u_{ij})\). Using induction on \(k\), we will show that if \(B\) is weakly \(\theta\)-orthogonal with \(\frac{\pi}{3} < \theta \leq \frac{\pi}{2}\), if the columns of \(\mathcal{B}\) satisfy (6), and if \(B\) is \(\frac{\pi}{4}\)-orthogonal, then \(\vec{B}\) can be obtained by permuting the columns of \(B\) and multiplying them by \(\pm 1\). Equivalently, we will show every column of \(U\) has exactly one component equal to \(\pm 1\) and all others equal to 0 (we call such a matrix a signed permutation matrix).

Assume that Theorem 2 holds for all \((k - 1)\)-D lattices with \(k > 2\). Let \(b_1, b_2, \ldots, b_k\) denote the columns of \(B\) and let \(\vec{b}_1, \vec{b}_2, \ldots, \vec{b}_k\) denote the columns of \(\vec{B}\). Since permuting the columns of \(\vec{B}\) does not destroy \(\frac{\pi}{4}\)-orthogonality, we can assume w.l.o.g. that \(\vec{b}_1\) is \(\vec{B}\)'s shortest vector. From Theorem 1, \(\vec{b}_1\) is also a shortest lattice vector. Further, using Corollary 1, \(\pm \vec{b}_1\) is contained in \(B\). Assume that \(b_\ell = \pm \vec{b}_1\) for some
\( \ell \in \{1, 2, \ldots, k\} \). Then

\[
B = \tilde{B} \begin{bmatrix}
    u_{11} & \cdots & u_{1\ell-1} & \pm 1 & u_{1\ell+1} & \cdots & u_{1k} \\
    \vdots & & \tilde{U}'_1 & 0 & \tilde{U}'_2 & & \\
    \vdots & & & & & & \\
\end{bmatrix}
\] (15)

Above, \( \tilde{U}'_1 \) is a \((k - 1) \times (\ell - 1)\) sub-matrix, where as \( \tilde{U}'_2 \) is a \((k - 1) \times (k - \ell)\) sub-matrix. We will show that \( u_{1j} = 0 \), for all \( j \in \{1, 2, \ldots, k\} \) with \( j \neq \ell \). Define

\[
\mathcal{B}_r = \begin{bmatrix} b_\ell & b_j \end{bmatrix}, \quad \tilde{\mathcal{B}}_r = \begin{bmatrix} \tilde{b}_1 & \sum_{i=2}^{k} u_{ij}\tilde{b}_i \end{bmatrix}.
\] (16)

Then, from (15) and (16),

\[
\mathcal{B}_r = \tilde{\mathcal{B}}_r \begin{bmatrix} \pm 1 & u_{1j} \\
0 & 1 \end{bmatrix}.
\]

Since \( \mathcal{B}_r \) and \( \tilde{\mathcal{B}}_r \) are related by a unimodular matrix, they both define bases of the same 2-D lattice. Further, \( \mathcal{B}_r \) is weakly \( \theta \)-orthogonal with \(|b_j| < \eta(\theta)||b_\ell||\), and \( \tilde{\mathcal{B}}_r \) is \( \frac{\pi}{3} \)-orthogonal. Invoking Theorem 2 for 2-D lattices, we can infer that \( u_{1j} = 0 \). It remains to be shown that \( \mathcal{U}' = [\mathcal{U}'_1, \mathcal{U}'_2] \) is also a signed permutation matrix, where

\[
\mathcal{B}' = \tilde{\mathcal{B}}' \mathcal{U}',
\]

with \( \mathcal{B}' = [b_1, b_2, \ldots, b_{\ell-1}, b_{\ell+1}, \ldots, b_k] \) and \( \tilde{\mathcal{B}}' = [\tilde{b}_2, \tilde{b}_3, \ldots, \tilde{b}_k] \). Observe that \( \det(\mathcal{U}') = \det(\mathcal{U}) = \pm 1 \).

Both \( \mathcal{B}' \) and \( \tilde{\mathcal{B}}' \) are bases of the same \((k - 1)\)-D lattice as \( \mathcal{U}' \) is unimodular. \( \tilde{\mathcal{B}}' \) is \( \frac{\pi}{3} \)-orthogonal, whereas \( \mathcal{B}' \) is weakly \( \theta \)-orthogonal and its columns satisfy (6). By the induction hypothesis, \( \mathcal{U}' \) is a signed permutation matrix. Therefore, \( \mathcal{U} \) is also a signed permutation matrix. \( \square \)

### 4.3 Proof of Theorem 3

Theorem 3 is a direct consequence of the following lemma.

**Lemma 1** Let \( \mathcal{B} = (b_1, b_2, \ldots, b_m) \) be a weakly \( \theta \)-orthogonal basis of a lattice, where \( \theta > \frac{\pi}{3} \). Then, for any integers \( u_1, u_2, \ldots, u_m \),

\[
\left\| \sum_{i=1}^{m} u_i b_i \right\| \geq \left( \frac{\sqrt{3}}{2} \right)^{m-1} \times \max_{i \in \{1, 2, \ldots, m\}} \| u_i b_i \|. \tag{17}
\]

Lemma 1 can be proved as follows. Consider the vectors \( b_1 \) and \( b_2 \); the angle \( \theta \) between them lies in the interval \((\frac{\pi}{3}, \frac{\pi}{2})\). Recall from (10) that

\[
\| u_1 b_1 + u_2 b_2 \|^2 \geq \left( \| u_1 \| b_1 \| - \| u_2 \| \| b_2 \| \right)^2 + \| u_1 \| \| u_2 \| \| b_1 \| \| b_2 \| .
\]

Consider the expression \((y-x)^2 + yx\) with \( 0 \leq x \leq y \). For fixed \( y \) this expression attains its minimum value of \((\frac{3}{4})y^2\) when \( x = \frac{y}{2} \). By setting \( y = \| u_1 \| \| b_1 \| \) and \( x = \| u_2 \| \| b_2 \| \) w.l.o.g, we can infer that

\[
\| u_1 b_1 + u_2 b_2 \| \geq \frac{\sqrt{3}}{2} \max_{i \in \{1, 2\}} \| u_i b_i \| .
\]
Since \( B \) is weakly \( \theta \)-orthogonal, the angle between \( u_k b_k \) and \( \sum_{i=1}^{k-1} u_i b_i \) lies in the interval \( (\pi/2, \pi) \) for \( k = 2, 3, \ldots, m \). Hence (17) follows by induction.

We now proceed to prove Theorem 3 by invoking Lemma 1. Define \( \Delta = \left( \frac{\sqrt{3}}{2} \right)^{m-1} \). For any \( j \in \{1, 2, \ldots, m\} \), we have

\[
\|b_j\| = \left\| \sum_{i=1}^{m} u_{ij} \tilde{b}_i \right\| \geq \Delta \max_{i \in \{1, 2, \ldots, m\}} \|u_{ij}\| \geq \Delta \min_{i \in \{1, 2, \ldots, m\}} \|\tilde{b}_i\| \max_{i \in \{1, 2, \ldots, m\}} |u_{ij}|.
\]

Since \( B \) and \( \tilde{B} \) are both weakly \( \theta \)-orthogonal with \( \theta > \pi/3 \), \( \min_{i \in \{1, 2, \ldots, m\}} \|\tilde{b}_i\| = \min_{i \in \{1, 2, \ldots, m\}} \|b_i\| \).

Therefore,

\[
\Delta \max_{i \in \{1, 2, \ldots, m\}} |u_{ij}| \leq \frac{\|b_j\|}{\min_{i \in \{1, 2, \ldots, m\}} \|\tilde{b}_i\|} \leq \frac{\max_{i \in \{1, 2, \ldots, m\}} \|b_i\|}{\min_{i \in \{1, 2, \ldots, m\}} \|\tilde{b}_i\|} = \Delta \kappa(B).
\]

Thus, \( |u_{ij}| \leq \kappa(B) \), for all \( i \) and \( j \).

5 Random Lattices and SVP

In several applications, the orthogonality of random lattice bases and the length of the shortest vector \( \lambda(L) \) in a random lattice \( L \) play an important role. For example, in certain wireless communications applications involving multiple transmitters and receivers, the received message ideally lies on a lattice spanned by a random basis [7]. The random basis models the fluctuations in the communication channel between each transmitter-receiver pair. Due to the presence of noise, the ideal received message is retrieved by solving a CVP. The complexity of this problem is controlled by the orthogonality of the random basis [1]. Random bases are also employed to perform error correction coding [28] and in cryptography [28]. The level of achievable error correction is controlled by the shortest vector in the lattice.

In this section, we determine the \( \theta \)-orthogonality of random bases. This result immediately lets us identify conditions under which a random basis contains (with high probability) the shortest lattice vector.

Before describing our results on random lattices and bases, we first review some known properties of random lattices and then list some powerful results from random matrix theory.

5.1 Known Properties of Random Lattices

Consider an \( m \)-D lattice generated by a random basis with each of the \( m \) basis vectors chosen independently and uniformly from the unit ball in \( \mathbb{R}^n \) \((n \geq m)\).\(^2\) With \( m \) fixed and with \( n \to \infty \), the probability that the random basis is Minkowski-reduced tends to 1 [11]. Thus, as \( n \to \infty \), the random basis contains a shortest vector in the lattice almost surely. Recently, [3] proved that as \( n - m \to \infty \), the probability that a random basis is LLL-reduced \( \to 1 \). [3] also showed that a random basis is LLL-reduced with non-zero probability when \( n - m \) is fixed with \( n \to \infty \).

5.2 Known Properties of Random Matrices

Random matrix theory, a rich field with many applications [6, 12], has witnessed several significant developments over the past few decades [12, 18, 19, 30]. We will invoke some of these results to derive some

---

\(^2\)The \( m \) vectors form a basis because they are linearly independent almost surely.
new properties of random bases and lattices; the paper [6] provides an excellent summary of the results we mention below.

Consider an \( n \times m \) matrix \( B \) with each element of \( B \) an independent identically distributed random variable. If the variables are zero-mean Gaussian distributed with variance \( \frac{1}{n} \), then we refer to such a \( B \) as a Gaussian random basis. If the variables take on values in \( \{-\frac{1}{\sqrt{n}}, \frac{1}{\sqrt{n}}\} \) with equal probability, then we term \( B \) to be a Bernoulli random basis. We denote the eigenvalues of \( B^T B \) by \( \psi_{2i}^2, i = 1, 2, \ldots, m \). Gaussian and Bernoulli random bases enjoy the following properties.

1. For both Gaussian and Bernoulli \( B \), \( B^T B \)'s smallest and largest eigenvalues, \( \psi_{\text{min}}^2 \) and \( \psi_{\text{max}}^2 \), converge almost surely to \( (1 - \sqrt{c})^2 \) and \( (1 + \sqrt{c})^2 \) respectively as \( n, m \to \infty \) and \( \frac{m}{n} \to c < 1 \) [6, 12, 30].

2. Let \( \epsilon > 0 \) be given. Then, there exists an \( N_\epsilon \) such that for every \( n > N_\epsilon \) and \( r > 0 \),

\[
P \left( |\psi_{\text{min}}| \leq \left( 1 - \sqrt{\frac{m}{n}} \right) - (r + \epsilon) \right) \leq e^{-nr^2 \rho},
\]

\[
P \left( |\psi_{\text{max}}| \geq \left( 1 + \sqrt{\frac{m}{n}} \right) + (r + \epsilon) \right) \leq e^{-nr^2 \rho},
\]

with \( \rho = 2 \) for Gaussian \( B \) and \( \rho = 16 \) for Bernoulli \( B \) [6, 18].

In essence, a random matrix’s largest and smallest singular values converge, respectively, to \( 1 \pm \sqrt{\frac{m}{n}} \) almost surely as \( n, m \to \infty \) and lie close to \( 1 \pm \sqrt{\frac{m}{n}} \) with very high probability at finite (but sufficiently large) \( n \).

### 5.3 New Results on Random Lattices

We now formally state the new properties of random lattices mentioned in the Introduction plus several additional corollaries. The key step in proving these properties is to relate the condition number of a random basis to its \( \theta \)-orthogonality (see Lemma 2). A matrix’s condition number is defined as the ratio of the largest to the smallest singular value. Then we invoke the results in Section 5.2 to quantify the \( \theta \)-orthogonality of random bases. Finally we invoke previously deduced properties of nearly orthogonal lattice bases.

We wish to emphasize that we prove our statements only for lattices which are not full-dimensional. Our computational results suggest these statements are not true for full-dimensional lattices. Further, Sorkin [31] proves that with high-probability, Gaussian random matrices are not nearly orthogonal when \( m > n/4 \).

See the paragraph after Corollary 3 for more details.

**Lemma 2** Consider an arbitrary \( n \times m \) real-valued matrix \( B \), with \( m \leq n \), whose largest and smallest singular values are denoted by \( \psi_{\text{max}} \) and \( \psi_{\text{min}} \), respectively. Then the columns of \( B \) are \( \theta \)-orthogonal with

\[
\theta = \sin^{-1} \left( \frac{2 \psi_{\text{max}} \psi_{\text{min}}}{\psi_{\text{min}}^2 + \psi_{\text{max}}^2} \right).
\]

The proof is given in Section 5.4. The value of \( \theta \) in (20) is the best possible in the sense that there is a \( 2 \times 2 \) matrix \( B \) with singular values \( \psi_{\text{min}} \) and \( \psi_{\text{max}} \) such that the angle between the two columns of \( B \) is given by (20). Note that for large \( \frac{\psi_{\text{max}}}{\psi_{\text{min}}} \) (that is, small condition number), the \( \theta \) in (20) is close to \( \frac{\pi}{4} \). Thus, Lemma 2 quantifies our intuition that a matrix with small condition number should be nearly orthogonal.

By combining Lemma 2 with the properties of random matrices listed in Section 5.2, we can immediately deduce the \( \theta \)-orthogonality of an \( n \times m \) random basis. See Section 5.4.2 for the proof.
Theorem 4 Let $B$ denote an $n \times m$ Gaussian or Bernoulli random basis. If $m \leq cn$, $0 \leq c < 1$, then as $n \to \infty$, $B$ is $\theta$-orthogonal almost surely with

$$\theta = \sin^{-1}\left(\frac{1 - c}{1 + c}\right).$$

(21)

Further, given an $\epsilon > 0$, there exists an $N_c$ such that for every $n > N_c$ and $r > 0$, $B$ is $\theta$-orthogonal,

$$\theta = \sin^{-1}\left(\frac{1 - c}{1 + c} - \frac{3\sqrt{3}}{4}(r + \epsilon)\right),$$

(22)

with probability greater than $1 - 2e^{-\frac{n^2}{\rho}}$, where $\rho = 2$ for Gaussian $B$ and $\rho = 16$ for Bernoulli $B$.

The value of $\theta$ in (21) is not the best possible in the sense that for a given value of $c$, a random $n \times m$ Gaussian matrix with $m \leq cn$ would be $\theta'$-orthogonal (with high probability) for some $\theta' > \theta$ (see Figure 2). The reason is that the $\theta$ predicted by Lemma 2 is satisfied by all matrices. However, Theorem 4 is restricted to random matrices.

Theorem 4 allows us to bound the length of the shortest non-zero vector in a random lattice.

Corollary 2 Let the $n \times m$-matrix $B = (b_1, b_2, \ldots, b_m)$, with $m \leq cn$ and $0 \leq c < 1$, denote a Gaussian or Bernoulli random basis for a lattice $L$. Then the shortest vector’s length $\lambda(L)$ satisfies

$$\lambda(L) \geq \frac{1 - c}{1 + c}$$

almost surely as $n \to \infty$.

Each column of a Bernoulli $B$ is unit-length by construction. For Gaussian $B$, it is not difficult to show that all columns have length 1 almost surely as $n \to \infty$. Hence Corollary 2 is an immediate consequence of Theorem 4 and (2). Corollary 2 implies that in random lattices that are not full-dimensional, it is easy to obtain approximate solutions to the SVP (within a constant factor). This is because for random lattices in $\mathbb{R}^n$ with dimension $n(1 - \epsilon)$, $\lambda(L)$ is greater than $\epsilon$ times the length of the shortest basis vector (approximately). Compare this with Daudé and Vallée’s [9] result that in random full-dimensional lattices in $\mathbb{R}^n$, $\lambda(L)$ is at least $O(1/\sqrt{n})$ times the length of the shortest basis vector with high probability.

By substituting $\theta = \frac{\pi}{4}$ into Theorem 4 and then invoking Corollary 1, we can deduce sufficient conditions for a random basis to be $\frac{\pi}{4}$-orthogonal.

Corollary 3 Let the $n \times m$-matrix $B$ denote a Gaussian or Bernoulli random basis for lattice $L$. If $\frac{m}{n} \leq c < (7 - \sqrt{48})$ ($\approx 0.071$), then $B$ is $\frac{\pi}{4}$-orthogonal almost surely as $n \to \infty$. Further, given an $\epsilon > 0$, there exists an $N_c$ such that for every $n > N_c$ and $0 < r > 0$, $B$ is $\frac{\pi}{4}$-orthogonal with probability greater than $1 - 2e^{-\frac{n^2}{\rho}}$, where $\rho = 2$ for Gaussian $B$ and $\rho = 16$ for Bernoulli $B$.

Figure 2 illustrates that, in practice, an $n \times m$ Gaussian and Bernoulli random matrix is nearly orthogonal for much larger values of $\frac{m}{n}$ than our results claim. Our plots suggest that the probability for a random basis to be nearly orthogonal sharply transitions from 1 to 0 for $\frac{m}{n}$ values in the interval $[0.2, 0.25]$. Sorkin [31] has shown us that if the columns of $B$ represent points chosen uniformly from the unit sphere in $\mathbb{R}^n$ (one can obtain such points by dividing the columns of a Gaussian matrix by their norms), then the best possible $\frac{m}{n}$ value for random $n \times m$ matrices to be $\frac{\pi}{4}$-orthogonal is $\frac{m}{n} = 0.25$. Further, if $m/n > 0.25$, $B$ is almost surely not $\frac{\pi}{4}$-orthogonal as $n \to \infty$. For large $n$, the columns of a Gaussian matrix almost surely have length 1, and thus behave like points chosen uniformly from the unit sphere in $\mathbb{R}^n$. Therefore, as $n \to \infty$, random $n \times n/4$ Gaussian matrices are almost surely $\frac{\pi}{4}$-orthogonal.
5.4 Proof of Results on Random Lattices

This section provides the proofs for Lemma 2 and Theorem 4.

5.4.1 Proof of Lemma 2

Our goal is to construct a lower-bound for the angle between any column of $B$ and the subspace spanned by all the other columns in terms of the singular values of $B$. Clearly, if $\psi_{\min} = 0$, then the columns of $B$ are linearly dependent. Hence, (20) holds as $B$’s columns are $\theta$-orthogonal with $\theta = 0$. For the rest of the proof, we will assume that $\psi_{\min} \neq 0$.

Consider the singular value decomposition (SVD) of $B$

$$B = X\Psi Y,$$  \hspace{1cm} (23)

where $X$ and $Y$ are $n \times m$ and $m \times m$ real-valued matrices respectively with orthonormal columns, and $\Psi$ is a $m \times m$ real-valued diagonal matrix. Let $b_i$ and $x_i$ denote the $i$-th column of $B$ and $X$ respectively, let $y_{ij}$ denote the element from the $i$-th row and $j$-th column of $Y$, and let $\psi_i$ denote the $i$-th diagonal element of $\Psi$. Then, (23) can be rewritten as

$$[b_1 \ b_2 \ldots \ b_m] = [x_1 \ x_2 \ldots \ x_m] \begin{pmatrix} \psi_1 & 0 & \ldots & 0 \\ 0 & \psi_2 & \ldots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & \ldots & \ldots & \psi_m \end{pmatrix} \begin{pmatrix} y_{11} & y_{12} & \ldots & y_{1m} \\ y_{21} & y_{22} & \ldots & y_{2m} \\ \vdots & \ddots & \ddots & \vdots \\ y_{m1} & \ldots & \ldots & y_{mm} \end{pmatrix}.$$  \hspace{1cm} (24)

We now analyze the angle between $b_1$ (w.l.o.g) and the subspace spanned by $\{b_2, b_3, \ldots, b_m\}$. Note that

$$b_1 = \sum_{i=1}^{m} \psi_i y_{i1} x_i.$$  \hspace{1cm} (25)

Let $\tilde{b}_1$ denote an arbitrary non-zero vector in the subspace spanned by $\{b_2, b_3, \ldots, b_m\}$. Then,

$$\tilde{b}_1 = \sum_{k=2}^{m} \alpha_k b_k = \sum_{k=2}^{m} \alpha_k \sum_{i=1}^{m} \psi_i y_{ik} x_i = \sum_{i=1}^{m} x_i \psi_i \sum_{k=2}^{m} \alpha_k y_{ik},$$

for some $\alpha_k \in \mathbb{R}$ with $\sum_k |\alpha_k| > 0$. Let $\tilde{y}_{i1} = \sum_{k=2}^{m} \alpha_k y_{ik}$. Then,

$$\tilde{b}_1 = \sum_{i=1}^{m} \psi_i \tilde{y}_{i1} x_i.$$  \hspace{1cm} (26)

Let $\tilde{\theta} \geq \theta$ denote the angle between $b_1$ and $\tilde{b}_1$. Then,

$$\cos \tilde{\theta} = \frac{\langle b_1, \tilde{b}_1 \rangle}{\|b_1\| \|\tilde{b}_1\|} = \frac{\left| \left\langle \sum_{i=1}^{m} \psi_i y_{i1} x_i, \sum_{i=1}^{m} \psi_i \tilde{y}_{i1} x_i \right\rangle \right|}{\| \sum_{i=1}^{m} \psi_i y_{i1} x_i \| \| \sum_{i=1}^{m} \psi_i \tilde{y}_{i1} x_i \|} = \frac{\left| \sum_{i=1}^{m} \psi_i^2 y_{i1}^2 \tilde{y}_{i1} \right|}{\sqrt{\sum_{i=1}^{m} \psi_i^2 y_{i1}^2} \sqrt{\sum_{i=1}^{m} \psi_i^2 \tilde{y}_{i1}^2}}.$$  \hspace{1cm} (27)
where the orthonormality of $X$’s columns is used to obtain (25) from (24). Let $y_i, i = 1, 2, \ldots, m$, and $\tilde{y}_1$ denote column vectors

$$
y_i := \begin{bmatrix} y_{i1} \\ y_{i2} \\ \vdots \\ y_{im} \end{bmatrix} \quad \text{and} \quad \tilde{y}_1 := \begin{bmatrix} \tilde{y}_{11} \\ \tilde{y}_{21} \\ \vdots \\ \tilde{y}_{m1} \end{bmatrix}.
$$

Since $\tilde{y}_1 = \sum_{k=2}^{m} \alpha_k y_k$,

$$\tilde{y}_1^T y_1 = 0.$$ 

Then (25) can be rewritten using matrix notation as

$$\cos \tilde{\theta} = \frac{|y_1^T \Psi^2 \tilde{y}_1|}{\sqrt{y_1^T \Psi^2 y_1 \sqrt{\tilde{y}_1^T \Psi^2 \tilde{y}_1}}}.$$ (26)

with $\Psi^2 := \Psi^T \Psi$. The angle $\tilde{\theta}$ is minimized when the right hand side of (26) is maximized.

For arbitrary $B$ with only the singular values known (that is, $\Psi$ is known), the $\theta$-orthogonality of $B$ is given by solving the following constrained optimization problem.

$$\cos \theta = \max_{y_1, \tilde{y}_1} \frac{|y_1^T \Psi^2 \tilde{y}_1|}{\sqrt{y_1^T \Psi^2 y_1 \sqrt{\tilde{y}_1^T \Psi^2 \tilde{y}_1}}} \quad \text{such that} \quad \tilde{y}_1^T y_1 = 0.$$ (27)

Wielandt’s inequality [14, Thm. 7.4.34] states that if $A$ is a positive definite matrix, with $\gamma_{\min}$ and $\gamma_{\max}$ denoting its minimum and maximum eigenvalues (both are positive), then

$$|x^T Ay|^2 \leq \left(\frac{\gamma_{\max} - \gamma_{\min}}{\gamma_{\max} + \gamma_{\min}}\right)^2 (x^T Ax)(y^T Ay)$$

for every pair of orthogonal vectors $x$ and $y$ (equality holds for some pair of orthogonal vectors). In our problem, $A = \Psi^2$, $x = \tilde{y}_1$, $y = y_1$, $\gamma_{\max} = \psi_{\max}^2$ and $\gamma_{\min} = \psi_{\min}^2$. Therefore, using Wielandt’s inequality and (27), we have

$$\cos \theta = \frac{\psi_{\max}^2 - \psi_{\min}^2}{\psi_{\max}^2 + \psi_{\min}^2}.$$ 

Hence

$$\sin \theta = \frac{2\psi_{\max} \psi_{\min}}{\psi_{\max}^2 + \psi_{\min}^2},$$ (28)

which proves (20).

\section*{5.4.2 Proof of Theorem 4}

The first part of Theorem 4 follows easily. From Section 5.2, we can infer that with $m \leq cn$, $0 \leq c < 1$, both $\psi_{\min} \geq 1 - \sqrt{c}$ and $\psi_{\max} \leq 1 + \sqrt{c}$ almost surely as $n \to \infty$. Invoking Lemma 2 and substituting $\psi_{\min} = 1 - \sqrt{c}$ and $\psi_{\max} = 1 + \sqrt{c}$ into (20), it follows that as $n \to \infty$, $B$ is $\theta$-orthogonal almost surely with $\theta$ given by (21).
We now focus on proving the second part of Theorem 4. Let \( d = \sqrt{c} \), and define

\[
G(d) := \frac{1 - d^2}{1 + d^2}.
\]

We first show that for \( \delta \geq 0 \),

\[
G(d + \delta) \geq G(d) - \frac{3\sqrt{3}}{4}\delta. \tag{29}
\]

Using the mean value theorem,

\[
G(d + \delta) = G(d) + G'(d + \tilde{\delta}) \delta, \quad \text{for some } \tilde{\delta} \in (0, \delta), \tag{30}
\]

with \( G' \) denoting the derivative of \( G \) with respect to \( d \). Further,

\[
G'(d) = \frac{-4d}{(1 + d^2)^2} \geq -\frac{3\sqrt{3}}{4}, \quad \text{for } d > 0. \tag{31}
\]

One can verify the inequality above by differentiating \( G'(d) \), and observing that \( G'(d) \) is minimized when \( 3d^4 + 2d^2 - 1 = 0 \). The only positive root of this quadratic equation is \( d^2 = 1/3 \) or \( d = 1/\sqrt{3} \). Combining (30) and (31), we obtain (29).

From the results in Section 5.2, it follows that the probability that both minimum and maximum singular values of \( B \) satisfy

\[
|\psi_{\min}| \geq 1 - (\sqrt{c} + r + \epsilon) \quad \text{and} \quad |\psi_{\max}| \leq 1 + (\sqrt{c} + r + \epsilon) \tag{32}
\]

is greater than \( 1 - 2e^{-\frac{\epsilon^2}{r}} \). When (32) holds, \( B \) is at least \( \sin^{-1}(G(\sqrt{c} + r + \epsilon)) \)-orthogonal. This follows from (20). Invoking (29), we can infer that \( B \) is \( \theta \)-orthogonal with \( \theta \) as in (22).

\[\square\]

6 JPEG Compression History Estimation (CHEst)

In this section, we review the JPEG CHEst problem that motivates our study of nearly orthogonal lattices, and describe how we use this paper’s results to solve this problem. We first touch on the topic of digital color image representation and briefly describe the essential components of JPEG image compression.

6.1 Digital Color Image Representation

Traditionally, digital color images are represented by specifying the color of each pixel, the smallest unit of image representation. According to the trichromatic theory [29], three parameters are sufficient to specify any color perceived by humans.\(^3\) For example, a pixel’s color can be conveyed by a vector \( w_{RGB} = (w_R, w_G, w_B) \in \mathbb{R}^3 \), where \( w_R, w_G, \) and \( w_B \) specify the intensity of the color’s red (R), green (G), and blue (B) components respectively. Call \( w_{RGB} \) the RGB encoding of a color. RGB encodings are vectors in the vector space where the R, G, and B colors form the standard unit basis vectors; this coordinate system is called the RGB color space. A color image with \( M \) pixels can be specified using RGB encodings by a matrix \( P \in \mathbb{R}^{3 \times M} \).

\(^3\)The underlying reason is that the human retina has only three types of receptors that influence color perception.
6.2 JPEG Compression and Decompression

To achieve color image compression, schemes such as JPEG first transform the image to a color encoding other than the RGB encoding and then perform quantization. Such color encodings can be related to the RGB encoding by a color-transform matrix \( C \in \mathbb{R}^{3 \times 3} \). The columns of \( C \) form a different basis for the color space spanned by the R, G, and B vectors. Hence an RGB encoding \( w_{\text{RGB}} \) can be transformed to the \( C \) encoding vector as \( C^{-1}w_{\text{RGB}} \); the image \( P \) is mapped to \( C^{-1}P \). For example, the matrix relating the RGB color space to the ITU.BT-601 YCbCr color space is given by [27]

\[
\begin{bmatrix}
    w_Y \\
    w_{Cb} \\
    w_{Cr}
\end{bmatrix}
= \begin{bmatrix}
    0.299 & 0.587 & 0.114 \\
    -0.169 & -0.331 & 0.5 \\
    0.5 & -0.419 & -0.081
\end{bmatrix}
\begin{bmatrix}
    w_R \\
    w_G \\
    w_B
\end{bmatrix}.
\]

(33)

The quantization step is performed by first choosing a diagonal, positive (non-zero entries are positive), integer quantization matrix \( Q \), and then computing the quantized (compressed) image from \( C^{-1}P \) as \( P_c = \left\lfloor Q^{-1}C^{-1}P \right\rfloor \), where \( \lfloor . \rfloor \) stands for the operation of rounding to the nearest integer. JPEG decompression constructs \( P_i = CQP_c = CQ\left\lfloor Q^{-1}C^{-1}P \right\rfloor \). Larger \( Q \)’s achieve more compression but at the cost of greater distortion between the decompressed image \( P_i \) and the original image \( P \).

In practice, the image matrix \( P \) is first decomposed into different frequency components \( P = \{P_1, P_2, \ldots, P_k\} \), for some \( k > 1 \) (usually \( k = 64 \)), during compression. Then, a common color transform \( C \) is applied to all the sub-matrices \( P_1, P_2, \ldots, P_k \), but each sub-matrix \( P_i \) is quantized with a different quantization matrix \( Q_i \). The compressed image is \( P_c = \{P_{c,1}, P_{c,2}, \ldots, P_{c,k}\} = \{\left\lfloor Q_{1}^{-1}C^{-1}P_1 \right\rfloor, \left\lfloor Q_{2}^{-1}C^{-1}P_2 \right\rfloor, \ldots, \left\lfloor Q_{k}^{-1}C^{-1}P_k \right\rfloor\} \), and the decompressed image is \( P_d = \{CQ_1P_{c,1}, CQ_2P_{c,2}, \ldots, CQ_kP_{c,k}\} \).

During compression, the JPEG compressed file format stores the matrix \( C \) and the matrices \( Q_i \)’s along with \( P_c \). These stored matrices are utilized to decompress the JPEG image, but are discarded afterward. Hence we refer to the set \( \{C, Q_1, Q_2, \ldots, Q_k\} \) as the compression history of the image.

6.3 JPEG CHEst Problem Statement

This paper’s contributions are motivated by the following question: Given a decompressed image \( P_d = \{CQ_1P_{c,1}, CQ_2P_{c,2}, \ldots, CQ_kP_{c,k}\} \) and some information about the structure of \( C \) and the \( Q_i \)’s, can we estimate the color transform \( C \) and the quantization matrices \( Q_i \)’s? As \( \{C, Q_1, Q_2, \ldots, Q_k\} \) comprises the compression history of the image, we refer to this problem as JPEG CHEst. An image’s compression history is useful for applications such as JPEG recompression [5, 22, 23].

6.4 Near-Orthogonality and JPEG CHEst

The columns of \( CQ_iP_{c,i} \) lie on a 3-D lattice with basis \( CQ_i \) because \( P_{c,i} \) is an integer matrix. The estimation of \( CQ_i \)’s comprises the main step in JPEG CHEst. Since a lattice can have multiple bases, we must exploit some additional information about practical color transforms to correctly deduce the \( CQ_i \)’s from the \( CQ_iP_{c,i} \)’s. Most practical color transforms aim to represent a color using an approximately rotated reference coordinate system. Consequently, most practical color transform matrices \( C \) (and thus, \( CQ_i \)) can be expected to be almost orthogonal. We have verified that all \( C \)’s used in practice are weakly \((\frac{\pi}{3} + \epsilon)\)-orthogonal, with \( 0 < \epsilon < \frac{\pi}{6} \).\(^4\) Thus, nearly orthogonal lattice bases are central to JPEG CHEst.

\(^4\)In general, the stronger assumption of \( \frac{\pi}{3} \)-orthogonality does not hold for some practical color transform matrices.
6.5 Our Approach

Our approach is to first estimate the products \( CQ_i \) by exploiting the near-orthogonality of \( C \) and to then decompose \( CQ_i \) into \( C \) and \( Q_i \). We will assume that \( C \) is weakly \( \left( \frac{\pi}{3} + \epsilon \right) \)-orthogonal, \( 0 < \epsilon \leq \frac{\pi}{6} \).

6.5.1 Estimating the \( CQ_i \)'s

Let \( B_i \) be a basis of the lattice \( \mathcal{L}_i \) spanned by \( CQ_i \). Then, for some unimodular matrix \( U_i \), we have

\[
B_i = CQ_i U_i. \tag{34}
\]

If \( B_i \) is given, then estimating \( CQ_i \) is equivalent to estimating the respective \( U_i \).

Thanks to our problem structure, the correct \( U_i \)'s satisfy the following constraints. Note that these constraints become increasingly restrictive as the number of frequency components \( k \) increases.

1. The \( U_i \)'s are such that \( B_i U_i^{-1} \) is weakly \( \left( \frac{\pi}{3} + \epsilon \right) \)-orthogonal.

2. The product \( U_i B_i^{-1} B_j U_j^{-1} \) is diagonal with positive entries for any \( i, j \in \{1, 2, \ldots, k\} \).
   
   This is an immediate consequence of (34).

If in addition, \( B_i \) is weakly \( \left( \frac{\pi}{3} + \epsilon \right) \)-orthogonal, then

3. The columns of \( U_i \) corresponding to the shortest columns of \( B_i \) are the standard unit vectors times \( \pm 1 \).
   
   This follows from Corollary 1 because the columns of both \( B_i \) and \( CQ_i \) indeed contain all shortest vectors in \( \mathcal{L}_i \) up to multiplication by \( \pm 1 \).

4. All entries of \( U_i \) are \( \leq \kappa(B_i) \) in magnitude.
   
   This follows from Theorem 3.

We now outline our heuristic.

(i) Obtain bases \( B_i \) for the lattices \( \mathcal{L}_i, i = 1, 2, \ldots, k \). Construct a weakly \( \left( \frac{\pi}{3} + \epsilon \right) \)-orthogonal basis \( B_\ell \) for at least one lattice \( \mathcal{L}_\ell \), \( \ell \in \{1, 2, \ldots, k\} \).

(ii) Compute \( \kappa(B_\ell) \).

(iii) For every unimodular matrix \( U_\ell \) satisfying constraints 1, 3 and 4, go to step (iv).

(iv) For \( U_\ell \) chosen in step (iii), test if there exist unimodular matrices \( U_j \) for each \( j = 1, 2, \ldots, k, j \neq \ell \) that satisfy constraint 2. If such a collection of matrices exists, then return this collection; otherwise go to step (iii).

For step (i), we simply use the LLL algorithm to compute LLL-reduced bases for each \( \mathcal{L}_i \). Such bases are not guaranteed to be weakly \( \left( \frac{\pi}{3} + \epsilon \right) \)-orthogonal, but in practice, this is usually the case for a number of the \( \mathcal{L}_i \)'s. Instead of LLL, the method proposed in [25] could be also employed (as suggested by the referees).

In contrast to the LLL, [25] always finds a basis that contains the shortest lattice vector in low-dimensional lattices (up to 4-D) such as the \( \mathcal{L}_i \)'s in our problem. In step (iv), for each frequency component \( j \neq \ell \), we compute the diagonal matrix \( D_j \) with smallest positive entries such that \( \bar{U}_j = B_j^{-1} B_\ell U_\ell^{-1} D_j \) is integral, and then test whether \( \bar{U}_j \) is unimodular. If not, then for the given \( U_\ell \), no appropriate unimodular matrix \( U_j \) exists.

The overall complexity of the heuristic is determined mainly by the number of times we repeat step (iv), which equals the number of distinct choices for \( U_\ell \) in step (iii). This number is typically not very large.
Table 1: Number of unimodular matrices satisfying constraints 3 and 4 for small $\kappa$.

because in step (i), we are usually able to find some weakly $(\frac{\pi}{3} + \epsilon)$-orthogonal basis $B_l$ with $\kappa < 2$. In fact, we enumerate all unimodular matrices satisfying constraints 3 and 4 and then test constraint 1. (In practice, one can avoid enumerating the various column permutations of a unimodular matrix). Table 1 provides the number of unimodular matrices satisfying constraint 4 alone and also constraints 3 and 4. Clearly, constraints 3 and 4 help us to significantly limit the number of unimodular matrices we need to test, thereby speeding up our search.

Our heuristic returns a collection of unimodular matrices $\{U_l\}$ that satisfy constraints 1 and 2; of course, they also satisfy constraints 3 and 4 if the corresponding $B_l$’s are weakly $(\frac{\pi}{3} + \epsilon)$-orthogonal. From the $U_l$’s, we compute $CQ_l = B_l U_l^{-1}$. If constraints 1 and 2 can be satisfied by another solution $\{U'_l\}$, then it is easy to see that $U'_l \neq U_l$ for every $i = 1, 2, \ldots, k$. In Section 6.5.3, we will argue (without proof) that constraints 1 and 2 are likely to have a unique solution in most practical cases.

### 6.5.2 Splitting $CQ_i$ into $C$ and $Q_i$

Decomposing the $CQ_i$’s into $C$ and $Q_i$’s is equivalent to determining the norm of each column of $C$ because the $Q_i$’s are diagonal matrices. Since the $Q_i$’s are integer matrices, the norm of each column of $CQ_i$ is an integer multiple of the corresponding column norm of $C$. In other words, the norms of the $j$-th column ($j \in \{1, 2, 3\}$) of different $CQ_i$’s form a sub-lattice of the 1-D lattice spanned by the $j$-th column norm of $C$. As long as the greatest common divisor of the $j$-th diagonal values of the matrices $Q_i$’s is 1, we can uniquely determine the $j$-th column of $C$; the values of $Q_i$ follow trivially.

### 6.5.3 Uniqueness

Does JPEG CHEst have a unique solution? In other words, is there a collection of matrices

$$(C', Q_1', Q_2', \ldots, Q'_k) \neq (C, Q_1, Q_2, \ldots, Q_k)$$

such that $C'Q'_i$ is a weakly $(\frac{\pi}{3} + \epsilon)$-orthogonal basis of $L_i$ for all $i \in \{1, 2, \ldots, k\}$? We believe that the solution can be non-unique only if the $Q_i$’s are chosen carefully. For example, let $Q$ be a diagonal matrix with positive diagonal coefficients. Assume that for $i = 1, 2, \ldots, k$, $Q_i = \alpha_i Q$, with $\alpha_i \in \mathbb{R}$ and $\alpha_i > 0$. Further, assume that there exists a unimodular matrix $U$ not equal to the identity matrix $I$ such that $C' = CQU$ is weakly $(\frac{\pi}{3} + \epsilon)$-orthogonal. Define $Q'_i = \alpha_i I$ for $i = 1, 2, \ldots, k$. Then $C'Q'_i$ is also a weakly $(\frac{\pi}{3} + \epsilon)$-orthogonal basis for $L_i$. Typically, JPEG employs $Q_i$’s that are not related in any special way. Therefore, we believe that for most practical cases JPEG CHEst has a unique solution.
6.5.4 Experimental Results

We tested the proposed approach using a wide variety of test cases. In reality, the decompressed image $P_d$ is always corrupted with some additive noise. Consequently, to estimate the desired compression history, the approach described above was combined with some additional noise mitigation steps. Our algorithm provided accurate estimates of the image’s JPEG compression history for all the test cases. We refer the reader to [22, 23] for details on the experimental setup and results.

7 Discussion and Conclusions

In this paper, we derived some interesting properties of nearly orthogonal lattice bases and random bases. We chose to directly quantify the orthogonality of a basis in terms of the minimum angle $\theta$ between a basis vector and the linear subspace spanned by the remaining basis vectors. When $\theta \geq \frac{\pi}{4}$ radians, we say that the basis is nearly orthogonal. A key contribution of this paper is to show that a nearly orthogonal lattice basis always contains a shortest lattice vector. We also investigated the uniqueness of nearly orthogonal lattice bases. We proved that if the basis vectors of a nearly orthogonal basis are nearly equal in length, then the lattice essentially contains only one nearly orthogonal basis. These results enable us to solve a fascinating digital color imaging problem called JPEG compression history estimation (JPEG CHEst).

The applicability of our results on nearly orthogonal bases is limited by the fact that every lattice does not necessarily admit a nearly orthogonal basis. In this sense, lattices that contain a nearly orthogonal basis are somewhat special.

However, in random lattices, nearly orthogonal bases occur frequently when the lattice is sufficiently low-dimensional. Our second main result is that an $m$-D Gaussian or Bernoulli random basis that spans a lattice in $\mathbb{R}^n$, with $m < 0.071n$, is nearly orthogonal almost surely as $n \rightarrow \infty$ and with high probability at finite but large $n$. Consequently, a random $n \times 0.071n$ lattice basis contains the shortest lattice vector with high probability. In fact, based on [31], the bound 0.071 can be relaxed to 0.25, at least in the Gaussian case.

We believe that analyzing random lattices using some of the techniques developed in this paper is a fruitful area for future research. For example, we have recently realized (using Corollary 3) that a random $n \times 0.071n$ lattice basis is Minkowski-reduced with high probability [8].

Acknowledgments

We thank Gabor Pataki for useful comments and for the reference to Gauss’s work in Vazirani’s book. We also thank the editor Alexander Vardy and the anonymous reviewers for their thorough and thought-provoking reviews; our work on random lattices was motivated by their comments. Finally, we thank Gregory Sorkin who gave us numerous insights into the properties of random matrices.

References

Figure 2: Empirical probability that a $n \times m$ Gaussian or Bernoulli random matrix is $\frac{\pi}{3}$-orthogonal. At $n = 256$, 512, 1024, and 2048 and at $m$ indicated by circles (for Gaussian) and triangles (for Bernoulli), we tested 200 randomly generated matrices. The empirical probability is the fraction of random matrices that were $\frac{\pi}{3}$-orthogonal.
